Previous lectures have emphasized the things we lost by going to C:

- Many operations that would safely cause an error in C0, like dereferencing NULL or reading outside the bounds of an array, are undefined in C — we cannot predict or reason about what happens when we have undefined behaviors.
- It is not possible to capture or check the length of C arrays.
- In C, pointers and arrays are the same — and we declare them like pointers, writing `int *i`.
- The C0 types `string, char*` and `char[]` are all represented as pointers to `char` in C.
- C is not garbage collected, so we have to explicitly say when we expect memory to be freed, which can easily lead to memory leaks.

In this lecture, we will endeavor to look on the bright side and explore some of the new things that C gives us. But remember: with great power comes great responsibility. Today we will look at the different ways that C represents numbers and the general, though mostly implementation-defined, properties of these numbers that we frequently count on.

1 Numbers in C

In addition to the undefined behavior resulting from bad memory access (dereferencing a NULL pointer or reading outside of an array), there are other undefined behaviors in C. In particular:

- Division by zero is undefined. (In C0, this always causes an exception.)
• Shifting left or right by negative numbers or by too-large a number is undefined. (In C0, this always causes an exception.)

• Left-shifting a negative value is undefined. (In C0, this is permitted.)

• Arithmetic overflow for signed types like int is undefined. (In C0, this is defined as modular arithmetic.)

This has some strange effects. If x and y are signed integers, then the expressions $x < x+1$ and $x/y == x/y$ are either true or undefined (due to signed arithmetic or overflow, respectively). So the compiler is allowed to pretend that these expressions are just true all the time. The compiler is also allowed to behave the same way C0 does, returning false in the first case when x is the maximum integer and raising an exception in the second case when y is 0. The compiler is also free to check for signed integer overflow and division by zero and start playing Rick Astley’s “Never Gonna Give You Up” if either occurs, though this last option is unlikely in practice. Undefind behavior is unpredictable — it can and does change dramatically between different computers, different compilers, and even different versions of the same compiler.

The fact that signed integer overflow is undefined is particularly annoying. A check like $(x + 1 > x)$, which was a perfectly acceptable way to check that x was not int_max() in C0, is now a check that the compiler is allowed to optimize to just true, because the result of this expression, in C, is either true or undefined.

There are two ways of coping with signed integer overflow being undefined. One option is to use unsigned types, which are required to obey the laws of modular arithmetic: unsigned int instead of int. As an example, consider a simple function to compute Fibonacci numbers. There are even faster ways of doing this, but what we do here is to allocate an array on the stack, fill it with successive Fibonacci numbers, and finally return the desired value at the end.

```c
unsigned int fib(unsigned int n) {
    unsigned int A[n+2]; /* stack-allocated array A */
    A[0] = 0;
    A[1] = 1;
    for (unsigned int i = 0; i <= n-2; i++)
    return A[n]; /* deallocates A just before actual return */
}
```

There’s another solution, particular to the compiler, gcc, that we usually use to compile C programs. This compiler (as well as other modern C
compilers like clang, has a flag -fwrapv. When we compile with -fwrapv, then the compiler promises it will treat overflow from addition and multiplication as signed two’s complement modular arithmetic, exactly like C0 does.

2 Implementation-defined Behavior

In addition to int, which is a signed type, there are the signed types short and long, and unsigned versions of each of these types — short is smaller than int and long is bigger. The numeric type char is smaller than int and always takes up one byte. The maximum and minimum values of these numeric types can be found in the standard header file <limits.h>.

C, annoyingly, does not define whether char is signed or unsigned. A signed char is definitely signed, a unsigned char is unsigned. The type char can be either signed or unsigned — this is implementation defined.

It is often very difficult to say useful and precise things about the C programming language, because many of the features of C that we have to rely on in practice are not part of the C standard. Instead, they are things that the C standard leaves up to the implementation — implementation defined behaviors. Implementation-defined behaviors make it quite difficult to write code on one computer that will compile and run on another computer, because the other compiler may make completely different choices about implementation-defined behaviors.

The first example we have seen is that, while a char is always exactly one byte, we don’t know whether it is signed or unsigned — whether it can represent integer values in the range \([-128, 128]\) or integer values in the range \([0, 256]\). And it is even worse, because a byte can be more than 8 bits! If you really want to mean “8 bits,” you should say octet.

In this class we are going to rely on a number of implementation-defined behaviors. For example, you can always assume that bytes are 8 bits on the computers we’re using for this class in this decade. When it is important to not rely on integer sizes being implementation-defined, it is possible to use the types defined in <stdint.h>, which defines signed and unsigned types of specific sizes. In the systems that you are going to use for programming, you can reasonably expect a common set of implementation-defined behaviors: char will be an 8-bit integer (maybe signed, maybe unsigned) and so on.

This chart describes how the <stdint.h> types match up to the standard C types in most modern C compilers:

<td>int16_t</td>
</tr>
<tr>

</tr>
<tr>
<td>long</td>
<td>int64_t</td>
</tr>
</tbody>
</table>

However, please remember that we cannot count on this correspondence behavior in all C compilers!

There is another crucial numerical type: size_t, is the type used to represent memory sizes and array indices. The sizeof(ty) operation in C actually returns just the size of a type in bytes, so malloc and xmalloc actually take one argument of type size_t and calloc and xcalloc take two arguments of type size_t. As we approach the third decade of the 21st century, we’re increasingly using 64-bit systems and not dealing with 32-bit systems anymore. On 32-bit systems, size_t is usually 4-byte, 32-bit unsigned integer. We now usually expect size_t to be a 64-bit, 8-byte unsigned integer.

3 Casting Between Numeric Types

Now that we’ve introduced a bunch of different integer types, we need to see how to work with multiple integer types in the same program.

We go from one integer type to another by casting values. Here’s an example:

```
unsigned char x = 240;
int y = (int)x;
```

We convert the value in the unsigned char variable x (i.e., 240) to a value of type int by casting it to an int with (int)x. What value will y contain? Well, 240 of course! Note however that these two 240 have different representations in the computer: x represents 240 as 0xf0 because it is a char, which is 8 bits long; instead, y represents 240 as 0xffffffff since the type int is 32 bits long (on modern computers). This looks more dramatic with negative numbers:

```
signed char x = -3; // x is -3 (= 0xfd)
int y = (int)x;     // y is -3 (0xffffffff)
```

Note that in both cases the cast performs sign extension.

In these examples, the value being cast (240 and -3, respectively) was representable as a value of new type — both 240 and -3 are valid ints. But
Lecture 21: Types in C

what if it isn’t? This is when things get tricky. What happens depends on whether the new type is signed or unsigned.

If the new type is unsigned and has a number of bits that is smaller than or equal to the original type, the least significant bits are retained:

```c
int x = INT_MAX; // x is 2147483647 (= 0x7FFFFFFF)
unsigned char y = (unsigned char)x; // y is 255 (=0xFF)
```

Clearly INT_MAX is larger than any char, and therefore we are throwing away the 24 most significant bits and keeping just the 8 least significant bits. Here’s another example:

```c
signed char x = -3; // x is -3 (= 0xFD)
unsigned char y = (unsigned char)x; // y is 253 (= 0xFD)
```

Here, -3 is not representable with an unsigned type. So, its 8 bits are interpreted as an unsigned char. Notice that in both cases, the value held in the new type is different than the original value.

If the new type is unsigned and has a larger number of bits than the original type, the value is sign-extended:

```c
signed char x = -3; // x is -3 (= 0xFD)
unsigned int y = (unsigned int)x; // y is 4294967293 (= 0xFFFFFFFF)
```

The last situation to consider is when the new type is signed, as in:

```c
int x = INT_MAX; // x is 2147483647 (= 0x7FFFFFFF)
signed char y = (signed char)x; // y is ...
```

Again, INT_MAX is too big to fit into a char. The result of this cast is implementation-defined. A common way a compiler may handle this is to simply discard the most significant bits, in which case the result would be 0xFF, i.e., -1.

In summary, casting between numeric types works as follows in C:

- If the new type can represent the value, the value is preserved.
- If the new type can’t represent the value,
  - if the new type is unsigned,
    * if the new type is smaller or the same, the least significant bits are retained.
    * if the new type is bigger, the bits are sign-extended.
  - if the new type is signed, the result is implementation-defined.

The C standard allows omitting many of the casts in these examples (but not all). Such omitted casts are called implicit and will be filled in by
the compiler. Most often, this behind-the-scene casting achieves exactly what we want, but not always. When the compiler adds casts that are different from what we had in mind, this often results in obscure bugs that can take hours to fix. To avoid this, it’s best to program defensively by writing explicit casts whenever in doubt.

Here are a few pitfalls you should watch out for when writing code that involves different numerical types:

- When you cast from a large signed (or unsigned) type to a small signed (or unsigned) type, make sure that the type you’re casting to can represent the number. (So, for instance, you can cast the int 17 to an signed char, but don’t cast the int 1000 to a signed char, because a signed char can only represent numbers between -128 and 127, inclusive.)

- When you add, subtract, multiply, divide, compare, or do bitwise operations involving multiple variables, it’s best to make sure that all the numbers you’re working with have the same size and same signedness. One important “gotcha” here: if you just write the number 4, it’s treated as an int by default, so writing

  ```c
  int64_t i = 1 << 40;
  ```

  will actually be undefined behavior, because 1 is (implementation-defined to be) a 32-bit quantity that can only be shifted by numbers between 0 and 31, inclusive. The fix, in this situation, is to write:

  ```c
  int64_t i = 1;
  i = i << 40;
  ```

4 Other Types In C

C introduces a number of other types as well that we didn’t have in C0. In particular, many C programs use enum types, union types, and the floating point types, float and double, which are used to represent fractional numbers like 0.25. You’ll learn much more about these other C types in later courses, like 15-213, but here are the basics.

4.1 Floating Point

The C type float allows writing numbers such as 0.1 and 3.14159265 as well as 2.2035 \times 10^{-27} (entered as 2.2035E-27) that have a fractional component. It also allows writing very large numbers such as 10^{20} that are
Lecture 21: Types in C

not representable as int’s. float provides floating point numbers as a way to work with numbers other than integers, in particular (some) rational numbers. The size of a float is implementation-defined, although it is typically 32 bits in modern computers. Those 32 bits is all that is available to represent floating point numbers — the same as int’s — but the range these numbers are drawn from is much wider: $10^{20}$ and $-10^{20}$ can both be entered as float’s although much larger than INT_MAX and much smaller than INT_MIN respectively, and so is $10^{-20}$. What gives? Precision.

The following simple program divides $10^{20}$ by $10^{10}$ and multiplies the outcome by $10^{10}$. We expect the final result to be $10^{20}$.

```c
int main() {
    float x = 10E20;
    float y = 10E10;
    printf("%f\n", (x/y)*y);
}
```

Instead, it outputs 999999949672133165056.000000 — almost $10^{20}$ but not quite.

C offers another type for floating point numbers, double, which stands for double precision (its size is again implementation-defined and typically 64 bits in current hardware). The above example works as expected if we replace float with double, but a similar example which uses bigger numbers will suffer from the same problem: double precision is not infinite precision.

Precision loss during calculations, as just witnessed, makes it all but impossible to reason about programs that use floating point numbers. This is why float was left out of C0.

Here’s another example:

```c
for (float res = 0.0; res != 5.0; res += 0.1) {
    printf("res = %f\n", res);
}
printf("Done!\n");
```

We would expect the loop to run some 50 times, then exit and print Done!. Instead, it keeps running, printing ever larger values of res:

```
# a.out
res = 0.000000
res = 0.100000
res = 0.200000
... [elided]
res = 2.600000
res = 2.700000
```
After a few iterations, the value of res starts deviating from what we expect — a single decimal digit followed by zeros — and eventually passes 5.0 because it is never equal to that value. How is this possible with simple numbers like 0.1 and 5.0? These numbers, as we entered them in the program, are in decimal. The compiler automatically converts them into binary using a very similar procedure as what we saw for integers. Take 0.1. We obtain the fractional part (or mantissa) by repeatedly multiplying this number by 2 and harvesting the digit to the left of the decimal point until we get 0:

\[
\begin{align*}
0.1 \times 2 &= 0.2 \quad \text{yields} \quad 0 \\
0.2 \times 2 &= 0.4 \quad \text{yields} \quad 0 \\
0.4 \times 2 &= 0.8 \quad \text{yields} \quad 0 \\
0.8 \times 2 &= 1.6 \quad \text{yields} \quad 1 \quad \text{subtract} \quad 1 \\
0.6 \times 2 &= 1.2 \quad \text{yields} \quad 1 \quad \text{subtract} \quad 1 \\
0.2 \times 2 &= 0.4 \quad \text{yields} \quad 0
\end{align*}
\]

and so on. Notice that we have seen 0.2 before, and therefore the process repeats ... infinitely. The number 0.0, at which point we would stop, never emerges. What is happening is that, while 0.1 has a finite mantissa in decimal (just one digit after the decimal point), it has an infinite mantissa in binary: 0.1\text{\small{10}} is a periodic number in binary — 0.0\text{\small{0011}}\text{\small{2}}. This means that a precise representation as a binary mantissa cannot be achieved with any fixed number of bits. Thus the value of x above is an approximation of 0.1 rather than exactly this number. It is printed out as \text{\small{0.100000}} thanks to rounding but, as we keep on adding it to itself with “res += x” errors accumulate since we are working with an approximation of 0.1, and these errors eventually manifest when printing res.

### 4.2 Union and enum types

As a way to introduce some additional features of C, consider a type of trees that carry their data in their leaves rather than in the inner nodes.
(we call them leafy trees and they are at the basis of data structures used in
the implementation of database management systems and in other areas of
computer science). A leafy tree can be a leaf carrying a value, it can be an
inner node with no value but left and right children, it can also be empty
which contains neither a value nor children.

Based on the fragment of C we know so far, we would use the following
type to define the nodes of a leafy tree with integer values:

```c
typedef struct ltree leafytree;
struct ltree {
    int nodetype;
    int data;
    leafytree *left;
    leafytree *right;
};
```

We use the field nodetype to distinguish the type of the node (a leaf, an
inner node, or empty). This representation wastes memory: inner nodes
do not make use of the data field, while left and right are meaningless
for a leaf, and furthermore all 3 for go unused for the empty tree. As we
will see shortly, C provides a mechanism to mitigate this problem.

Before examining it, let’s go back to nodetype: we need to pick three
values to denote the three types of nodes, but we use the space for an entire
int for them — more waste. C provides enum types as a way to shield the
programmer both from picking constants whose values are to all effects
irrelevant as long as they are distinct and in deciding exactly how much
memory to allocate. In our example, this is done through the declaration

```c
enum nodetype { INNER, LEAF, EMPTY };
```

From now on, we can use the mnemonic constants INNER, LEAF and EMPTY
as type indicators for our various nodes.

Union types provide a way to view an area of memory as having more
than one type. Here, the memory associated with a node needs to be viewed either as an int (for leaves) or as a pair of pointers (for inner nodes).
We can do so using the following declarations:

```c
typedef struct ltree leafytree;
struct innernode { // type of an inner node
    leafytree *left;
    leafytree *right;
};
```

1An alternative is to represent the empty leafy tree as NULL. We refrain from doing so
to make this example more interesting.
union nodecontent { // contents of a non-empty node:
    int data; // EITHER an int
    struct innernode node; // OR and inner node
};

struct ltree {
    enum nodetype type;
    union nodecontent content;
};

Here, struct innernode packages the two pointers needed for inner nodes. The type union nodecontent can contain either the integer data or the value node of type struct innernode — but not both. The compiler will decide how to organize the memory for this union type (on modern hardware, probably 16 byte viewed either as two 8-byte pointers or a 4-byte int and 12 unused bytes). Lastly, the definition of struct ltree contains the field type of enum type enum nodetype defined earlier, and the field content of union type union nodecontent.

We define an actual leafy tree as in the following example:

leafytree *T = malloc(sizeof(leafytree));
T->type = INNER;
T->content.node.left = malloc(sizeof(leafytree));
T->content.node.left->type = EMPTY;
T->content.node.right = malloc(sizeof(leafytree));
T->content.node.right->type = LEAF;
T->content.node.right->content.data = 42;

Note that the type fields are assigned the symbolic constants in our enum type. Notice also that we access the alternatives of a union type using the dot notation, as in T->content.node.left. It is left to the discipline of the programmer to use these fields consistently, for instance not to access the data component of an INNER node.

Before we are done with this example, let’s introduce a useful construct of C, especially in the presence of enum type definitions: the switch statement. The following recursive function adds all the values stored in (the leaves of) a leafy tree:

int add_tree(leafytree *T) {
    int n = 0;
    switch (T->type) {
    case INNER:
        n += add_tree(T->content.node.left);
        n += add_tree(T->content.node.right);
        break;
    }
The construct `switch` discriminates on the value of `T->type`, jumping to the appropriate `case` block. If a `case` block is not given for a value, the execution proceeds to the `default` block which is always the last (although a programmer may decide to omit it). Each block except the last typically needs to end with a `break` statement, otherwise the execution will proceed with the next block rather than exiting the `switch` statement.
5 Exercises

Exercise 1 (sample solution on page 14). Using one or more casts, write an expression that converts an integer \( x \) of type \texttt{short} into an integer \( y \) of type \texttt{unsigned int} in such a way that the least significant bits of \( y \) are exactly the same as those of \( x \), and the most significant bits of \( y \) are 0? For example (assuming a \texttt{short} is 16 bit and an \texttt{int} is 32 bits), if \( x \) is \texttt{0xABCD}, then \( y \) will be \texttt{0x0000ABCD}.

Exercise 2 (sample solution on page 14). Fill in the table with the cast that would result in the corresponding values and bit patterns. Assume that \texttt{char} is 1 byte, \texttt{short} is 2 bytes, and \texttt{int} is 4 bytes, as well as \texttt{gcc} implementation of casting, where going to a smaller size just truncates the bits to fit.

You are given \texttt{int} \( x = -15122 \); whose bit pattern is \texttt{0xFFFFC4EE}.

Exercise 3 (sample solution on page 14). The following casts are made. Identify which casts are implementation-defined. You may assume that a \texttt{char} is 1 byte, a \texttt{short} is 2 bytes, an \texttt{int} is 4 bytes, and a \texttt{long} is 8 bytes.

\texttt{int} \( x = 15122; \)
\texttt{char} \( c = (\texttt{char})x; \)
\texttt{unsigned short} \( s = x; \)
\texttt{unsigned int} \( y = x; \)
\texttt{long} \( l = (\texttt{long})x; \)
\texttt{unsigned long} \( k = (\texttt{unsigned int})x; \)
\texttt{uint64_t} \( z = x; \)

Exercise 4 (sample solution on page 14). The following function takes an integer month and returns a string that represents the month. For the integers 1, 3, 6, 10, and 12, what would the function return?

\texttt{char *}\texttt{month_to_string(int month) \{}
char *month_string;

switch (month) {
    case 1:
        month_string = "January";
        break;
    case 2:
        month_string = "February";
        break;
    case 3:
        month_string = "March";
    case 4:
        month_string = "April";
        break;
    case 5:
        month_string = "May";
        break;
    case 6:
        month_string = "June";
        break;
    case 7:
        month_string = "July";
        break;
    case 8:
        month_string = "August";
        break;
    case 9:
        month_string = "September";
        break;
    case 10:
        month_string = "October";
    case 11:
        month_string = "November";
    case 12:
        month_string = "December";
    default:
        month_string = "Invalid Month";
}

return month_string;
}
Sample Solutions

Solution of exercise 1 In order to accomplish this, we first have to make the value of \( x \) unsigned while preserving its bits. To do so, we cast it to an \texttt{unsigned short}. Then we can cast it to an \texttt{int}, which will have the effect of preserving its value since every \texttt{unsigned short} is representable a (signed) \texttt{int}. Thus, we need to write

\[
\texttt{unsigned int } y = (\texttt{unsigned int})(\texttt{unsigned short})x;
\]

Solution of exercise 2

<table>
<thead>
<tr>
<th>Value</th>
<th>Bit Pattern</th>
<th>C Expression</th>
</tr>
</thead>
<tbody>
<tr>
<td>-15122</td>
<td>0xC4EE</td>
<td>(short)x</td>
</tr>
<tr>
<td>4294952174</td>
<td>0xFFFFC4EE</td>
<td>(unsigned int)x</td>
</tr>
<tr>
<td>50414</td>
<td>0xC4EE</td>
<td>(unsigned short)x</td>
</tr>
<tr>
<td>-18</td>
<td>0xFFEE</td>
<td>(short)(signed char)x</td>
</tr>
</tbody>
</table>

For the last entry, it is important to go to a small signed type to just keep the EE on the end, and then cast it to a larger signed type to have sign extension occur.

Solution of exercise 3 Performing \((\texttt{char})x\) is implementation-defined. Whether \texttt{char} is signed or unsigned is implementation-defined, and in the case that it is signed, we are trying to place a value which does not fit into a signed value, so the result is implementation-defined.

Solution of exercise 4 It would return

- 1: "January",
- 3: "April",
- 6: "June",
- 10: "Invalid Month",
- 12: "Invalid Month".

The last two cases are missing a \texttt{break} statement, causing the switch to fall though the cases until it hits the default case.
